ABSTARCT:
The advances in three-dimensional structural analysis and computing resources have allowed the efficient and safe design of increasingly taller structure. These structures are the consequence of increasing urban densification and economical viability. The modern skyscraper has and will thus continue to feature prominently in the landscape of urban cities. The trend towards progressively taller structures has demanded a shift from the traditional strength based design approach of building to a focus on constraining the overall motion of the structure. Structural engineering have responded to this challenge of lateral control with a myriad of systems that achieve motion control while adhering to the overall architectural vision.

An investigation was carried out to understand the behavior of the different lateral system employed in today's skyscrapers. The investigation examined the structural behavior of the traditional moment frame, braced frame, integrated rigid brace system, brace frame with outriggers and finally braced frame with outriggers and belt truss. The advantages and disadvantages of all schemes were explored from both an architectural and structural efficiency standpoint. Prior to the computer modeling of each lateral system, each scheme was understood from behavioral standpoint to verify computer results. The study repeatedly illustrated that motion was the governing condition in all models, the increasing effect of wind load as the height of the building increases and change in design approach from strength to stiffness criterion.

INTRODUCTION

The achievement of structural process for tall structures shouldn't be an effortless project. Where, as building peak raises the value of lateral loads action rises in an
accelerating expense. There are two forms of lateral masses, wind and seismic loads. Wind load offers probably the most important lateral loading for brand new tall buildings, which have lightweight skeletons that cause uncomfortable horizontal movements for occupants. Additionally, wind is just not steady either with peak or with time and shouldn't be uniform over the perimeters of a constructing. So, windy climate creates a style of issues in tall structures, causing problem for buildings proprietor and engineers alike. The place immoderate vibration as a result of this load is a most important drawback in design and development of a state-of-the-art tall building. It will have to be confined to preclude each structural and nonstructural harm. The five important structural techniques used for the Tall constructions are:

1. Rigid body process
2. Rigid body with shear wall
3. Shear wall with opening
4. Outrigger system

Soil mechanics engineering is one of most important aspects of civil engineering involving the study of soil, its behaviour and application as an engineering material. Good soil engineering embodies the use of the best practices in exploration, testing, design and construction control, in addition to the basic idealized theories. With increasing load on soil due to construction of multi storeyed buildings there is a need to construct footing by conducting a test of their model in laboratory on the soil over which the foundation is to be laid.

Sand is one of the soils over which foundations are laid, so it is necessary to conduct experiments by placing different model footings over sand and find out their ultimate bearing capacity and based on these values, it can be incorporated on to the field and foundations can be laid. Square footings of different sizes are taken and model testing of these footings are conducted and the ultimate bearing capacity of different footings are found and on the basis of these values foundations are laid on sandy soils. These values can also be compared with theoretical analysis of Terzaghi and Meyerhof’s to check out the difference in values of ultimate bearing capacity between a theoretical and practical analysis.
inflexible frame method

encompass column and girders joined with the aid of moment resistant connections. The lateral stiffness of a inflexible-body bent will depend on the bending stiffness of the columns, girders and connections in the airplane of the bent

Shear Wall structure

it is a vertical continuous stiffening detail, that deform in bending mode. It is utilized in strengthened concrete structures and suitable to residential buildings and resorts.

Wall-body structures

1. When shear partitions are combined with rigid body the partitions, which are inclined to deflect in a flexural configuration, and the frames, which are likely to deflect in shear mode are restrained to undertake a customary deflected form by means of the horizontal pressure of the girders and slabs.

2. Consequences, the walls and frames engage horizontally, principally on the top to produce a stiffer and greater structure.

3. The interacting wall-body combo is suitable for constructing within the forty to 60 stories variety, good beyond that of rigid frames or shear walls alone
Outrigger-Braced Structures

Outriggers are connected directly to the core and to exterior columns. Used in reinforced concrete and steel buildings. Outriggers restrain the rotation of the core and convert part of the moment in the core into a vertical couple at the columns (columns restrained outriggers).

MAIN OBJECTIVES

1. Recommending a structural system for a certain building height, with the intention of limiting the wind drift to acceptable limits without paying a high premium in the quantity of structural material.

2. Presenting a comparative analysis between the most common structural systems of tall buildings built around the world within the past decades according to structural period and base shear values, drift and displacements.

3. Conceiving and applying the structural systems to extremely tall buildings is a practical demonstration of the engineer's confidence in the predictive ability of the analysis by commercial software.

METHODOLOGY

The methodology of this study is on comparison of behavior of structural systems on tall building is having various types of structural systems for various building heights, storey and load intensities. Shear walls and outriggers are also considered in this project and outriggers optimum location such that maximum utilization of this can be achieved is also given due importance. This study is intended to be helpful to clear the ambiguity in choosing the required type of system for a building as per the requirements of our building height, its location and its loading intensities

The model is a regular-shaped symmetrical plan with dimensions 49x49m. In all structural modeling, slab spans are assumed to be 7m, arranged in five bays in each direction. The plan has a 7x7 m central core opening. The storey height is assumed to be 3.5 m. The analysis used is a three-dimensional analysis of detailed finite element models. The columns and beams
were represented by frametype element, while shear walls and core components were represented by shell-type element.

Method of Analysis Equivalent Static Force Method

In the present study, the analysis of the structure is made for seismic loads using Equivalent Static Force Method because of symmetry of the structure, both in geometry and in mass.

Analysis of Structural Systems

ETABS software is used for the analysis of all structural systems by Equivalent Static Lateral Force Method for Zone Based on the method of analysis considered, lateral load calculations are made by the software itself and then applied to the structure to analyze. Hence the results are tabulated for the study of behavior of structural systems

Load Calculations

All the structural systems are subjected to three types of primary load cases as per the provisions of IS Code of Practice for Structural Safety of Buildings Loading Standard IS 875-1987 (Part I).

They are:

1. Dead Load (From IS: 875-1987(Part I))
2. Live Load (From IS: 875-1987(Part II))
3. Seismic Load (From IS: 1893-2002(Part I))

Type of Structure

Type of structure considered for the analysis is a ORDINARY reinforced concrete moment resisting frame. Hence response reduction factor, R=3.0 from Table 7 of IS 1893(Part I) 2002

Importance of Structure

As this structure can be used as general building, its importance of structure is represented by the

Importance factor, I=1.0 from Table 6 of IS 1893(Part I) 2002.

Soil Type

The average response acceleration coefficient (Sa/g) depends on the type of soil where the structure is located and the fundamental natural time period (Ta) of buildings. Hence knowing the soil type becomes important for the calculation of lateral load

Seismic Zones

In the present study, the behavior of all the structural systems is studied for all the seismic zones of India as per IS 1893(Part I) 2002. The Zone Factors and Seismic Intensities are as mentioned below as per Table 2 of IS 1893(Part I) 2002
Method of Analysis

In the present study, the analysis of the structure is made for lateral loads using Equivalent Static Force Method because of symmetry of the structure, both in geometry and in mass.

Assumptions

1. **Material:** Concrete is assumed to behave linearly elastic. The modulus of elasticity Ec will be taken as 4700f'c. Where, the specified compressive strength of concrete f'c is assumed equal to 40 Mpa, as used in practical applications of tall buildings.

2. **Participating components:** Only the primary structural components are assumed to participate in the overall behavior. The effects of secondary structural components and nonstructural components are assumed to be negligible; these include staircases, partitions, cladding, and openings.

3. **Floor slabs:** are assumed to be rigid in plane, with thickness equal to 30 cm in all models. This assumption causes the vertical elements at any floor level undergo the same components of translational displacement and rotation in the horizontal plane.

4. **Cracking:** The effect of cracking in reinforced concrete members due to flexural tensile stresses is represented by reducing moment of inertia,

5. **Constraints:** Supporting bases of all structural models are fixed supports.

6. **Loading:**
   i. **Gravity Loads:** Dead load is taken as 2kN/m², the building weight and its content is considered in the dead load and calculated based on material densities by the program. While, live load is taken as 4kN/m².
   ii. **Wind loads:** will be developed according to Indian standard.

7. **Wind loading:**
   Vb=50
   Terrain category =3

CONCLUSION AND ADDITIONAL SCOPE OF VENTURE

Situated On The confined study carried out, the next Conclusions Are Made:

1. Under the outcomes of wind masses, as the peak of the constitution raises, the lateral deflection and the overturning moment on the base increase. Tall buildings most likely require further structural fabric, with the intention to restrict the lateral deflection and face up to the overturning second, over and above that required for gravity masses handiest.

2. The important thing thought in limiting the wind go with the flow in a tall building
is via changing the structural type of the constructing into anything more inflexible and stable to confine the deformation and increase stability.

3. The stiffness (tension) and balance specifications emerge as extra important as the peak of the structure increases, and they're most often the dominant factors within the design.

4. As the building peak increases time interval has multiplied i.e., forty five% to fifty% increase will also be determined from the graphs for every addition of 15 reviews.

5. Maximum base shear on the base of the constructing broaden with the broaden in quantity of experiences. As a consequence it may be conclude that base shear relies by and large on seismic weight of the building.

6. The reduction in the displacement of rigid body with shear wall framed constitution is fifty % with recognize to R.C.C. Frame constitution, twenty five% in case of shear walls and sixty % when outrigger is used.

5.2 Structural programs conclusions.

The main conclusions of this comparative be taught, related to the effectivity of the offered 5 structural techniques and the capability of every method in limiting the wind float for a specified building height, can be summarized in the following:

- Inflexible frame procedure: The relatively excessive lateral flexibility calls for uneconomically tremendous contributors. It is not possible to accommodate the required depth of beams within the average ceiling area in tall rigid body. Not stiff as other three methods and viewed extra ductile and extra susceptible to wind failures. Inflexible body with shear wall the benefits of this procedure rely on the horizontal interplay, which is ruled with the aid of the relative stiffness of walls and frames and the peak of the structure. Because the constitution height and the stiffness of the frames develop, the interaction between partitions and frames increases. The foremost factor in choosing the have an impact on of the frames on the lateral stiffness of this approach is the peak. Because the structure height raises, the sharing of walls from the bottom shear decreases with appreciate to frames and extra interaction triggered between each of them. Shear wall/critical core procedure is more financial than rigid frame.
• A nice expand in flexural stiffness with appreciate to inflexible body and Outrigger procedure

• essentially the most financial method.

• Creates a much broader potent system for decreasing the overturning second within the core buildings. The outrigger structural systems now not only expert in controlling the top displacements but in addition play large position in reducing the inter storey drifts

The beneficial action is a operate of two causes:

1. The stiffness of the outrigger (Varies inversely with the outrigger distance from the bottom)

2. Its area within the constructing. An powerful method in case of finding out at what level the outriggers should be positioned as a way to have a highest have an impact on on the wind float. Very powerful in growing the constitution's flexural stiffness, nevertheless it does no longer develop its resistance to shear, which has to be carried in most cases via the core urged methods for exceptional Heights.
